ABSTRACT

The Milky Way has been generally considered to be representative of the numerous spiral galaxies inhabiting the local Universe, thus providing general and perhaps the most detailed constraints on numerical models of galaxy formation. We compare both the Milky Way and M31 galaxies to local external disk galaxies within the same mass range, using their locations in the planes drawn by V_{flat} versus M_K (the “Tully-Fisher” relation), j_{disk} (angular momentum) and the average Fe abundance, $[Fe/H]$, of stars in the outskirts of the galaxy. These relations are thought to be the imprints of the dynamical, star-formation, and accretion history of disk galaxies. We compare the best established Tully-Fisher relations and reconcile their slopes and zero points in the plane M_K - V_{flat} . We then compare the properties of local spirals from a representative sample to those of the Milky Way and M31 considering how these two galaxies would appear if observed at larger distances.

We find, for all relationships, that the Milky Way is systematically offset by $\sim 1\sigma$ or more from the distribution of comparable local galaxies: specifically, it shows a too small stellar mass, angular momentum, disk radius and outskirts stars $[Fe/H]$ ratio at a given V_{flat} , the latter being taken as a proxy for the total mass. In contrast with the Milky Way, M31 lies well within the mean of the fundamental relationships. On the basis of their locations in the $(M_K, V_{flat}$ and $R_d)$ volume, the fraction of spirals like the Milky Way is $7 \pm 1\%$, while M31 appears to be a “typical” spiral. As with M31, the bulk of local spirals show evidence for a formation history shaped mainly by merging. The Milky Way appears to have had an exceptionally quiet formation history and had escaped any significant merger over the last ~ 10 Gyrs which may explain why its angular momentum, stellar mass and $[Fe/H]$ (outskirts) are two to three times smaller than those of other local spirals. We conclude that the standard scenario of secular evolution driven by the accretion of gas and disk instabilities is generally unable to reproduce the properties of most (if not all) spiral galaxies, which are well represented by M31. However, the relatively recent proposal explaining the evolution of spiral galaxies through merging (the so-called “spiral rebuilding” scenario of Hammer et al. 2005) is consistent with the properties of both distant galaxies (e.g., stellar mass assembly through episodic IR luminous burst phases driven predominately by mergers) as well as to those of their descendants – the local spirals.

Subject headings: Galaxy: formation, Galaxies: evolution, Galaxies: formation, Galaxies: kinematics and dynamics, angular momentum

1. INTRODUCTION

Disk galaxies constitute the majority of the galaxy population observed in the local universe. They represent 70% of intermediate mass galaxies (stellar masses ranging from 3×10^{10} to $3 \times 10^{11} M_\odot$), which themselves include at least two-third of the present-day stellar mass (e.g., Hammer et al. 2005). Early studies of the Milky Way have led to a general description of the formation of a disk galaxy embedded in a halo (Eggen, Lynden-Bell, & Sandage 1962). Fall & Efstathiou (1980) set out a model of galaxy formation assuming that disks form from gas cooling and condensing in dark halos. Protogalactic disks are assumed to be made of gas containing substantial amount of angular momentum, which condenses into stars to form thin disks (Larson 1976). These disks then evolve only through secular processes. This so-called standard model successfully reproduces the flat rotation curves and the size of spirals (e.g., Mo et al. 1998, and reference therein). Such a model is (still) particularly adept at reproducing the properties of the Milky Way (e.g., Naab & Ostriker 2006, and references therein).

However, there are several outstanding difficulties with this standard scenario. One such difficulty is the so-called angu-

lar momentum problem. That is, simulated galaxies cannot reproduce the large angular momentum observed in nearby spiral galaxies (e.g., Steinmetz & Navarro 1999). Another is the assumed absence of collisions during and after the gas condensation process. Indeed, the hierarchical nature of the Λ CDM cosmology predicts that galaxies have assembled a significant fraction of their masses through collisions with other galaxies. It is likely that such collisions would easily destroy galactic disks (e.g., Toth & Ostriker 1992). Although the accretion of satellites may preserve the disk, it is also true that major collisions would certainly affect it dramatically. The key questions are then: Do major collisions always destroy disks? Can major collisions lead to the formation of new disks? Do these rebuilt or altered disks have properties consistent with those of local galaxies?

Observations of the merger rate evolution have now reached sufficient maturity to provide useful constraints on theory of galaxy evolution. For example, considering only galaxies with mass larger than $3 \times 10^{10} M_\odot$, the pair fraction of galaxies over the relative mass range of 1:1 to 1:3 at $z=0.6$ is $\sim 5 \pm 1\%$ (see Bell et al. 2006, and references therein). There is a remarkable agreement between different methods of estimating the pair fraction. All recent estimates, no matter what the technique, for example, two point correlation techniques

(Bell et al. 2006), or pair counts (Le Fèvre et al. 2000), or morphological classifiers (CAS: Conselice et al. 2003, GINI: Lotz et al. 2006) give consistent results. However, to constrain the cosmological evolution of the merger rate requires us to assume a characteristic time for a real pair to actually merge. Using arguments based on either dynamical friction (Binney & Tremaine 1987) or simple orbital time-scale (e.g., Bell et al. 2006), this time scale has been estimated to be about 0.35 Gyrs. Combining the pair fraction and characteristic time scale estimates suggests that for a present-day galaxy with a stellar mass larger than $3 \times 10^{10} M_{\odot}$, the chance it has experienced a major merger since $z=1$ is $50 \pm 17\%$, $75 \pm 25\%$ and 70% according to Lotz et al. (2006), Hammer et al. (2005), and Bell et al. (2006), respectively¹. Although less certain, integrating the merger rate to higher redshift implies that a typical bright galaxy may have experienced up to four to five major merging events since $z=3$ (Conselice et al. 2003).

The high frequency of major mergers may be a real problem for the standard theory of disk formation. Assuming that protogalactic disks lie in the distant universe, how can this be reconciled with an absence of major collisions? How can we explain the large fraction of local disks if major mergers (with mass ratio ranging from 1:1 to 1:3) unavoidably lead to the formation of an elliptical? Even at $z \leq 1$ the observations are challenging for the standard scenario. At least one third of intermediate mass galaxies at $z = 0.4-1$ have morphologies very discrepant from that of E/S0/Sp (Brinchmann et al. 1998; van den Bergh et al. 2001; Zheng et al. 2005). A similar fraction of distant galaxies possess complex velocity fields (26%, Flores et al. 2006; Puech et al. 2006) Peculiar morphology, and even more so, complex kinematics are almost certainly a result of on-going or recent mergers (Puech et al. 2006, 2007). If those galaxies were the progenitors of present-day ellipticals, this would lead to a much larger fraction of ellipticals than what is observed. Less than 10% of local intermediate mass galaxies are ellipticals (7% of galaxies brighter than $M_B < -20$; Conselice 2006), and they have formed the bulk of their stellar mass earlier, likely before $z=1$ (see Jimenez et al. 2006; Bernardi et al. 2006).

In summary, observations of distant galaxies pose a challenge to the standard secular scenario of spiral formation and evolution. The past history of the Milky Way is certainly lacking any major (and maybe even significant minor) interaction over at least the last 10 Gyrs. The validity of the standard scenario is highly dependent on whether or not the Milky Way is representative of the general population of spiral galaxies. In the following, we consider several probes of the past history of galaxies and compare the properties of the Milky Way and M31 to those of other spirals selected from a complete sample of nearby galaxies. For such a purpose, we cannot use optical spectral energy distribution or colors, which can be seriously affected by instantaneous star formation and extinction. To derive unambiguously the age and the metallicity requires studies of individual stars. Such analyses are therefore limited to only two massive galaxies, the Milky Way and M31.

Galaxy dynamics (disk velocity and angular momentum) is certainly an interesting avenue to test the history of galactic disks. The relationship between flat rotation velocity and stellar mass is very tight (e.g., Verheijen 2001) and reveals the

way the stellar mass has been assembled into galactic halos (see McGaugh 2005). The disk angular momentum (as the product of the disk radius to the rotational velocity) is a relic of events (or absence of events) which have been experienced by a galaxy. It is noteworthy that the standard scenario of disk formation shows some difficulties in reproducing both relationships (Tully-Fisher and $j_{\text{disk}}-V_{\text{flat}}$). On the basis of three dynamically related parameters (e.g., V_{flat} , M_K , used as a proxy of the stellar mass and R_d), one may identify whether the Milky Way (and M31) is representative or not of the general population of spiral galaxies.

Few studies have brought the question of the representativeness of the Milky Way to the attention of the astrophysical community. Flynn et al. (2006) showed that the Milky Way lies at 1σ from the Tully-Fisher relations of Verheijen (2001) and Pizagno et al. (2005). This conclusion needs to be firmly established. First because the two relations taken as references show different slopes and zero points, and second because I-band luminosity may be not accurate enough to robustly estimate the stellar mass. More surprising is the fact that the stellar content of the outskirts² of the Galaxy is apparently different (in its stellar chemical abundances and colors) from other spiral galaxies (Mouhcine et al. 2006; Zibetti et al. 2004). In the following, we attempt to establish a Tully-Fisher relation for local spirals that is consistent for all data sets, discuss the representativeness of M31 and the MW compared to local spiral galaxies, and as a results of these discussions, try to understand which scenario may apply to the entire ensemble of spiral galaxies.

The paper is organized as follows: in §2, we describe the properties of the Milky Way and M31 as if they were observed at larger distances; in §3, we concentrate on establishing an homogenized Tully-Fisher relation in (M_K-V_{flat}) which reconciles results from the SDSS (Pizagno et al. 2006) to those from Courteau (1997) and Verheijen (2001); in §4, we estimate how the Milky Way and M31 are representative of local spiral galaxies, on the basis of their positions in the $(M_K, V_{\text{flat}}$ and $R_d)$ volume; in §5, we discuss the general evidence that the Milky Way has had a “quiet” merging history; and finally, in §6, we compare the relative merits of the two disk formation scenarios (the standard scenario in which disk evolution is driven mainly by secular processes and another in which disk evolution is mainly driven by mergers of galaxies) in reproducing the characteristics of spiral galaxies. In this paper we adopt the Concordance cosmological parameters of $H_0=70 \text{ km s}^{-1} \text{ Mpc}^{-1}$, $\Omega_M=0.3$ and $\Omega_\Lambda=0.7$.

2. MILKY WAY AND M31 PROPERTIES FOR COMPARISON TO THOSE OF OTHER FIELD SPIRALS

2.1. Disk scale length R_d and angular momentum

Measurements of the Galactic disk scale length have lead to heterogeneous results since the early 90s. The difficulty in making such estimates probably results from the fact that we lie within it. Studies of the local stellar kinematics by Hipparcos and determinations of the dust and stellar mass distributions from all sky surveys (especially at IR wavelengths; see e.g., Drimmel & Spergel 2001, and references therein) have greatly improved the estimates of the Galactic disk scale length. Sackett (1997) convincingly showed that for most studies, the determination of R_0/R_d (where R_0 is the distance

¹ The differences, although small, are probably related to disagreements about the slope of the pair fraction redshift evolution, possibly due to different approaches in correcting for the effects of evolution or not.

² We use content of the *outskirts* to mean the stellar component that partially fills the dark halo from 5 to 30 kpc from the galaxy centre (see Brown et al. 2006, and the discussion in §5).

to the Galactic Center) is more secure observationally than that of R_d . Table 1 summarises the results for 15 estimates made since 1990, assuming the most accurate and direct estimate of R_0 (i.e., $R_0 = 7.62 \pm 0.32$ kpc, Eisenhauer et al. 2005, see also Appendix A). As Table 1 shows, very different approaches in estimating R_d produce a remarkably narrow range of values. Thus it now appears reasonable to derive a value for the Galactic disk scale length with an accuracy roughly similar to those derived for external galaxies. One study has however produced a very discrepant result. In this study, Mendez & van Altena (1998) have used low-latitude star-counts from the Guide Star Catalog to derive a value of R_d that is roughly twice that of other studies. While it is beyond the scope of this paper to argue for or against the robustness of any of these results, we note that it is quite surprising that shallow IR sky surveys such as COBE, DIRBE, 2MASS or DENIS (see Table 1) would find systematically low values of R_d in comparison. Given this and the relatively large quoted uncertainty in the study of Mendez & van Altena, we choose to consider the other 14 studies of Table 1 for our analysis. Even if we did include this study and take a weighted average of the ensemble of values, we note that it would make very little difference in the resulting value. In order to compare the value of R_d for the MW with measurements made in the optical (generally R or I band) for external galaxies, we adopt $R_d = 2.3 \pm 0.6$ kpc for the Milky Way. This value is within the 1σ uncertainty of 14 of the 15 estimates presented in Table 1. Because of possible systematic errors in we have adopted an uncertainty in the value of R_d that is twice the dispersion in the 14 estimates listed in Table 1. Because Reyl   & Robin (2001) determined a similar value for the exponential scale length of the thick disk (2.5 kpc), our adopted value applies for all the components with a disk geometry in the Milky Way and is probably close to what would be derived by an observer located outside the Milky Way.

For M31, we find that $R_d = 5.9 \pm 0.3$ kpc in R band (or 6.5 ± 0.3 kpc in B band), after correcting the original value in Walterbos & Kennicutt (1987) to a distance of 785 kpc (see McConnachie et al. 2005). Geehan et al. (2006) derive $R_d = 5.4$ kpc using R band data from Walterbos & Kennicutt (1987) and using the same supplemental data from Kent (1983). Using Spitzer observations, Barmby et al. (2006) find $R_d = 6.08 \pm 0.09$ kpc. These values are unlikely to be affected by the outer, star-forming ring of M31 which is weak at red wavelengths. Moreover, Barmby et al. carefully estimated the disk scale length excluding areas containing the outer ring and the most distant regions of the galaxy that are likely to be relatively more contaminated by emission from the sky background. Furthermore, the Spitzer data reach much lower relative surface brightness levels and thus extend much farther out in the galaxy light profile compare to the 2MASS data (Seigar et al. 2006). It is also likely that the latter may be affected by sky subtraction (see Barmby et al. 2006; Seigar et al. 2006). Given this situation, we adopt $R_d = 5.8 \pm 0.4$ kpc, where the adopted uncertainty accounts for the range of all the above estimates.

We adopt $V_{flat} = 220$ km s⁻¹ for the Milky Way (the current IAU standard, Kerr & Lynden-Bell 1986) and 226 km s⁻¹ for M31 (Carignan et al. 2006), adopting a conservative uncertainty of ± 10 km s⁻¹ in each value (see a detailed discussion in Appendix A). With these values, the angular momentum of M31 is 2.5 times higher than that of the Milky Way. The Milky Way has indeed a small disk scale length: at $V_{flat} =$

^bThe data sets used to derive the values of R_d . If the data are from optical or near-IR imaging, we list the central wavelengths used for the determination.

^cAll values are derived using a solar radius $R_0 = 7.62 \pm 0.32$ kpc (Eisenhauer et al 2005).

^dThe quoted uncertainties are the the maximum of the uncertainty quoted by the reference and of the uncertainty associated to the relation $R_d = R_0 \times (R_0/R_d)^{-1}$. Notice that for two studies, 5 and 8, uncertainties are not available.

220 km s⁻¹, galaxies in the SDSS show an average disk scale length of 4.75 kpc (Pizagno et al. 2006, see their Figure 20), twice the Milky Way value. M31 has a disk scale length rather similar to the average value for SDSS galaxies. These comparisons are based on what are presently the best estimates of the disk scale length and velocity for both the Milky Way and M31.

We are however cognisant of the fact that because these estimates have shown some variations in the past, future experiments (such as GAIA) will provide us with much more accurate, and perhaps even discrepant values. However given the concordance of previously determined values, this seems unlikely. Perhaps more problematic therefore is the fact that the disk scale length for the Milky Way has been estimated using methodologies different from that used for external galaxies, including M31. Some systematic uncertainty might affect these estimates when comparing them with external galaxies such as M31. To make a definite conclusion about the robustness of these estimates certainly requires a careful analysis of the complexity of both the Milky Way and M31, which is unfortunately beyond the scope of this paper. But we note that both the Milky Way and M31 have been fully imaged by COBE, DIRBE, 2MASS and DENIS for the former, and including Spitzer for the latter. Thus any possible systematic effects related to the extinction are unlikely to be a significant source of bias affecting the estimates of the ratio of the disk scale lengths of MW and M31. The robustness of the estimates for the Milky Way are also supported by the excellent agreement between IR measurements and models constrained by the detailed kinematics of various galactic components (see Table 1). Critically, both types of methods provide estimates which should be representative of the under-

lying stellar mass distribution. The Spitzer observations are also the best representation of the stellar mass distribution of M31 (Barmby et al. 2006). Little doubt should therefore be left that M31 disk has a significantly larger scale length than that of the Milky Way after comparing Barmby et al. value for M31 ($R_d=6.08\pm0.09$ kpc) to that of all sky surveys in IR for the Milky Way ($R_d=2.31\pm0.36$ kpc, see Table 1). We then assume in the following that the disk scale length of M31 is 2.5 ± 0.8 times that of the Milky Way. We note that the quoted uncertainty of 0.8 also takes into account possible systematic uncertainties in the disk scale lengths of the MW and M31.

2.2. Total absolute luminosity in K band and total stellar mass

Motivated by a strong desire to remove the imprint of the strong Milky Way signal from the very faint CMB fluctuations, the COBE experiment has provided an accurate value for the near IR luminosity of the Milky Way. Drimmel & Spergel (2001) derived an extinction corrected value for the K-band absolute magnitude of $M_K = -24.02$. This estimate is close to $M_K = -24.12$ found by Kent et al. (1991). Observations by Spitzer of M31 give $m(3.6\mu\text{m}) = -0.34$ after sky subtraction and integrating the light profile to large distances (Barmby et al. 2006). Barmby et al. assumes $K-m(3.6\mu\text{m}) = 0.3$, which implies $M_K = -24.51$. This value has not been corrected for extinction, the correction is -0.188 mag after applying the formalism of Tully et al. (1998). The values of the K-band absolute magnitude for both the Milky Way and M31 are robust and we adopt a conservative ± 0.1 magnitude for the uncertainty in each estimate.

One is able to derive stellar mass from M_K , using an empirical estimate of the color dependent M_{star}/L_K ratios (Bell et al. 2003). Using $B-V=0.79$ (Boissier 2000) and $B-R=1.5$ (Walterbos & Kennicutt 1987) for the Milky Way and M31, respectively, we derive $M_{\text{stellar}} = 5 \times 10^{10} M_\odot$ for the Milky Way and $10.3 \times 10^{10} M_\odot$ for M31. We have assumed $M_{K\odot} = 3.3$ (Bell et al. 2003) and a Kroupa IMF. For the Milky Way, our estimate is remarkably consistent with that of Flynn et al. (2006). For M31, our estimate is very close to the sum of the disk ($7.2 \times 10^{10} M_\odot$) and of the bulge ($3.2 \times 10^{10} M_\odot$) found by Geehan et al. (2006), and consistent with that of (Barmby et al. 2006, and Barmby, private communication). Because stellar mass estimates are subject to systematic uncertainties related to the choice of the IMF and the star-formation history through the adopted value of M/L_K , we choose in the following, to use M_K values as the foundation for making the comparison between the Milky Way, M31, and other local spirals. M_K will be used as a surrogate for the total stellar mass.

3. TOWARDS AN HOMOGENISED TULLY-FISHER RELATION FOR LOCAL SPIRALS

Our goal is to derive a Tully-Fisher relation for a representative sample of local galaxies. Measurements of a sample of SDSS galaxies ($H\alpha$ emission line) have been recently presented by Pizagno et al. (2006, hereafter called the SDSS sample). Although more needs to be done on this type of sample, the current sample includes all type of spirals from S0 to Sd, and the only morphological pre-selection is requirement that the galaxies be roughly edge-on ($b/a < 0.6$). The present data is apparently representative of the local galaxy luminosity function for $M_r < -20.5$ galaxies, and the completeness of this sample as it relates to our analysis will be addressed later in this section (see Figure 1 of Pizagno et al. 2006).

Among the best studied Tully-Fisher relation is the study

made by Verheijen (2001) based on a sample of Ursa Major cluster galaxies. Verheijen (2001) was able to calculate V_{flat} for 28 galaxies (hereafter called the Ursa Major sample) among 38 cluster members with HI data. Verheijen mentioned that V_{flat} can be estimated for all galaxies except those with rising velocity curves. Interestingly, such sources are flagged 3 in the Pizagno et al. (2006) study, and so for further comparison between the two samples, we will only keep flag 1 and 2 galaxies in the Pizagno et al. sample³. Indeed V_{flat} has generally been preferred to V_{max} , because conversely to the latter, it is not affected by the influence on the dynamics due to the bulge. Verheijen (2001) found a very tight correlation between M_K and V_{flat} and concluded that V_{flat} is the best proxy for the total galaxy mass.

Using different samples often leads to different slopes and zero points of the Tully-Fisher relation. This is illustrated by Figure 16 of Flynn et al. (2006) in which the individual Tully-Fisher relations from Bell & de Jong (2001) and Pizagno et al. (2005) are compared. Note however that Bell & de Jong sample is originally the Verheijen (2001) sample of galaxies for which stellar masses have been additionally estimated. Because SDSS and Ursa Major studies have applied the same procedure to estimate extinction corrections (the “mass dependent extinction” method, see Tully et al. 1998), we have been motivated to understand what are the causes of this difference.

In a panel of Fig. 1, we compare the K' magnitudes from Tully et al. (1996) and 2MASS for galaxies in Ursa Major. It shows an excellent agreement between the measurements, except for objects with $K' > 10$ for which K' data overestimate the K band luminosity by approximately 1 magnitude. Indeed, this problem was already noticed by Tully et al. (1996), who writes, “From inspection of the luminosity profiles, it is seen that there is a good agreement between the various passbands except that the K' material is truncated about 2 magnitudes shallower than the B, R, I material. It would require long exposures to reach surface brightness at K' comparable to those at optical bands”. Because in the 2MASS data base, magnitude errors from 0.02 to 0.08 are given, we have decided to adopt K magnitudes from 2MASS and then compare again the SDSS and Verheijen (2001) Tully-Fisher relations.

To do so, also requires a common method for estimating the rotation velocity of galaxies within the two samples. For this, we adopt the definition of V_{flat} as a good proxy for the total mass, because:

- of the remarkably tight baryonic Tully-Fisher relation over five decades in baryonic mass ($\sim V_{\text{flat}}^4$, see McGaugh, 2005). Such a tight relation must indicate that it is fundamentally a correlation between the maximum rotational velocity of the dark matter (V_{flat}) and the total baryonic mass inside that halo (e.g., Verheijen 2001);
- it is derived at large galacto-centric radii and is thus not affected by possible non-axisymmetric gas motions due to the presence of a bulge or a bar, as is often the case for the definition of V_{max} ;

³ Pizagno et al. (2006) classify galaxies into several distinct categories based on their rotation curves. Galaxies categorized as flag-1 are those with extended flat portions in velocity with increasing radius; flag-2 are those with rotation curves just reaching the turnover region, flag-3 have rotation curves still rising at the outermost measurement, while galaxies categorized as flag-4 have velocity curves that are not characterizable as rotation curves

FIG. 1.— *Left*: comparison between K band magnitudes from 2MASS (corrected by 0.044 mag, see Bessel 2005) to the K' value adopted by Verheijen (2001). Although they show a very good agreement for bright galaxies, the depth of the early measurements by Tully et al. (1996) over-estimate the luminosity of faint objects by approximately 1 magnitude. *Right*: Comparison of V_{80} (rotational velocity at 80% of the total I-band luminosity) from Pizagno et al. (2006) with V_{flat} from Verheijen (2001). Values are very similar for all objects except for 5 which are highly discrepant. The most discrepant object is NGC4138 which is a Sa galaxy with $V_{80}=187 \text{ km s}^{-1}$ and $V_{flat}=147 \text{ km s}^{-1}$. NGC4138 has a large bulge and so it is likely that V_{80} is closer to V_{max} than is V_{flat} . Other similarly discrepant objects show large inclinations in excess of 80° .

- the Milky Way and M31 have similar total masses⁴ (see Ibata et al. 2005, and references therein) and similar V_{flat} but different V_{max} . Please keep in mind however that the methods used to derive the total masses for both objects are different.

The right panel of Fig. 1 shows that estimates of V_{80} provide a good estimate for V_{flat} , at least for objects without large bulges and which are not purely edge-on. Indeed, the estimates of V_{80} have been adopted by Pizagno et al. (2006) to derive the Tully-Fisher relation, as it generally samples the rotational velocity at the optical radius and is approximately equivalent to three times the disk scale length.

Fig. 2 shows the Tully-Fisher relation for the two samples (Verheijen 2001, assuming the K magnitudes from 2MASS) and Pizagno et al. (2006, using only flag 1 and 2 galaxies). We have also superimposed the data from Courteau (1997, hereafter called the UGC sample), which includes 169 Sb-Sc UGC galaxies for which 2MASS photometry are available. For consistency, we consider only those galaxies having rotational velocities rising with radius by less than 10% of the adopted V_{flat} , which has been assumed to be the rotational velocity at three times the disk scale length (e.g., similar to the V_{80} of Pizagno et al. 2006, see Fig. 1). For all galaxies, to determine the absolute K-band magnitude, $M_K(AB)$ (where $M_K(AB)=M_K(\text{Vega})+1.87$), we adopt the K band magnitude from 2MASS and a single scheme for estimating the extinction (using the mass dependent extinction method Tully et al. 1998). In addition, all K-band absolute magnitudes have been k-corrected by $-2.1 \times z$ (Bell et al. 2003). The results are given in Table 2 for each of the three samples.

After our homogenization of data for the three samples, we find very good agreement between UGC and SDSS data, while the Ursa Major sample still shows a discrepant Tully-Fisher relation (Fig. 2 and Table 2). Even if the latter sample is much smaller than the other ones, this might present a significant problem for our purpose here. Fig. 3 shows the distribution of $M_K(AB)$ and $\log(V_{flat})$ for the three samples. Examination of Fig. 3 (and of Fig. 2) is illuminating: the Ursa

FIG. 2.— K band Tully-Fisher relation for three local galaxy samples: (blue) triangles (22 points, Verheijen 2001), (red) dots (105 points, Pizagno et al. 2006) and (black) squares (124 points, Courteau 1997). After revising K band magnitudes for the Verheijen's sample (see Fig. 1), the three samples define remarkably consistent relationships. The solid line is the fit of the three samples and the dashed lines represent the $\pm 1\sigma$ deviation about the best-fit line (0.47 mag). This result is very close to what has been derived from the single Pizagno et al. sample. The location of the Milky Way and M31 are marked as large green dots. In the insert at the top-left, we show the best-fit of the relation for each of the three samples (blue dashed line: Ursa Major; black-dashed line: UGC and red-dashed line: SDSS), illustrating the larger slope for the Ursa Major sample (see text and Table 2).

Major sample includes fainter and slower rotating galaxies than the other samples, and these galaxies tend to lie off of the relation defined by the brighter galaxies. This is probably due to low mass galaxies having large gas fractions (e.g., McGaugh 2005). This effect explains in a simple way the higher slope of the relation for Ursa Major. It is also illustrative to compare the K-band luminosity function of the Tully-Fisher samples to that of the population of local galaxies. The SDSS sample is indeed lacking small galaxies (see Fig. 3), especially below $\log(V_{80})=2.2$ (or equivalently with $M_K(AB) > -22$). Given the selection procedure adopted by Pizagno et al. (2006), as well as the large and statistically robust sample of the SDSS itself, we believe that it provides the best way to test the representativeness of the Milky Way among galaxies having parameters in the same range. The Milky Way has $\log(V_{flat})=2.34$ and Fig. 3 shows that the SDSS sample is limited to $\log(V_{flat})=2.5$, because very few spirals have rotational velocities in excess of 320 km s^{-1} . Within the range of $2.2 < \log(V_{flat}) < 2.5$, the distribution of velocities in the SDSS sample matches reasonably well what one would expect from a Schechter function. In the following, we have chosen this interval in which to characterize the representativeness of the Milky Way and M31 compared to the ensemble of local spiral galaxies.

4. REPRESENTATIVENESS OF THE MILKY WAY AND OF M31 IN THE (M_K , V_{FLAT} AND R_D) VOLUME

We confirm the results of Flynn et al. (2006) and find that the Milky Way lies at $\sim 1\sigma$ from the Tully-Fisher relation derived from the three local samples (Fig. 2). Such a discrepancy for the Milky Way is found in both the I and K band Tully-Fisher relations, so it is unlikely that it could be affected by an error in the magnitude or extinction estimate. Flynn et al. (2006) have extensively discussed the possible source of

⁴ with $M=7.5^{+2.5}_{-1.3} \times 10^{11} M_\odot$ for M31 (on the basis of the giant stream kinematics: Ibata et al. 2004; Geehan et al. 2006; on the basis of the satellite motions: Evans & Wilkinson 2000) and $M=5$ to $9 \times 10^{11} M_\odot$ (Battaglia et al. 2006), for the dark matter halo of the Milky Way, assuming either a Navarro Frenk & White or a Truncated Flat model, respectively.

TABLE 2
SLOPES, ZERO POINTS AND RESIDUAL SIGMAS (IN MAGNITUDE) OF THE FITTED TULLY-FISHER RELATIONS FOR THE URSA MAJOR, SDSS, AND UGC SAMPLES.

Sample	N_{points}	Zero point $\pm 1\sigma$ error	Slope $\pm 1\sigma$	σ_{res}	N_{points}	Zero point $\pm 1\sigma$ error	Slope $\pm 1\sigma$	σ_{res}
UMaj	22	2.37 2.17	-10.86 0.99	0.48	14	-13.86 4.47	-3.68 1.99	0.35
SDSS	105	-5.90 0.78	-7.16 0.34	0.47	79	-6.55 1.33	-6.88 0.57	0.38
UGC	124	-2.29 0.93	-8.77 0.41	0.44	97	-4.29 1.23	-7.92 0.53	0.36
All	251	-3.86 0.58	-8.07 0.26	0.47	190	-5.96 0.87	-7.17 0.37	0.38
SDSS/UGC	229	-4.50 0.60	-7.79 0.26	0.47	176	-5.60 0.91	-7.32 0.39	0.38

NOTE. — In columns 2, 3, 4, and 5, we give the best fit parameters including all galaxies for which the rotation curve is of sufficient quality or has the appropriate characteristics necessary to derive an accurate estimate of V_{flat} (see text for details). In the columns 6 through 9, we give the best fit relations only considering galaxies with $\log(V_{\text{flat}}) > 2.2$. Notice that the SDSS and UGC samples show very similar best fit parameters, and that limiting the sample to galaxies with high rotation velocities does not alter the best fit Tully-Fisher relations for these two samples.

FIG. 3.— Histograms of $M_K(\text{AB})$ (left) and $\log(V_{\text{flat}})$ (right) for the three samples, SDSS, Ursa Major and UGC (top to bottom respectively). The shaded histogram represents galaxies for which V_{80} appears to be an appropriate proxy for V_{flat} (see text for details). The top-left panel is very similar to the Figure 1 of Pizagno et al. and shows a deficiency of faint, slowly rotating galaxies with $M_r > -21$, $M_K(\text{AB}) > -22$ and $\log(V_{80}) < 2.2$. This is illustrated by the dashed line (top-right panel) showing the local $\log(V)$ number distribution function derived from the local K-band luminosity function (Cole et al., 2001 with $M_K^*(\text{AB}) = -22.4$ and a slope equal to -1) after assuming $(\log(V))^* = 2.35$ from the Tully-Fisher relation and $L_K \sim V^4$ following McGaugh (2005). Within $2.2 < \log(V_{\text{flat}}) < 2.5$ (vertical dotted lines), the SDSS sample provides a robust representation of the spiral galaxy distribution for comparison with the Milky Way.

systematic errors associated with such estimates, and found none convincing (see also Appendix A). The K band measurement by COBE (Drimmel & Spergel 2001) is certainly as accurate as K band measurements of external galaxies and accounts for extinction as well as for spiral arms on the opposite side of the galaxy from the Sun. The Milky Way K-band luminosity is half the average value for local spirals with similar V_{flat} . This can be translated into a similar factor in stellar mass. The difference (~ 0.7 mag) is much larger than the uncertainty in the total K-band luminosity estimate of the Milky Way. Besides this, M31 lies on the average relation delineated by other local spirals.

We also compute the specific angular momentum of the disk, estimating it using $j_{\text{disk}} = 2 R_d V_{\text{flat}}$, appropriate for a thin disk (see Mo et al. 1998). The only difference adopted here is the use of V_{flat} instead of V_{max} , as we believe it is a better proxy for the halo velocity (see previous section). Disk scale lengths are estimated in I band for the SDSS sample, K band for the Ursa major sample, and r band for the UGC

FIG. 4.— j_{disk} versus V_{flat} for galaxies in the three local samples (same symbols as in Fig. 2). Open stars represent the results from simulations of Steinmetz & Navarro (1999). The differences between the simulations and the data illustrate the difficulty of the standard model for disk formation and evolution in reproducing the angular momentum of spiral galaxies.

sample. We choose not to apply for an inclination correction to R_d values, such Dutton et al. (2006) have done, simply because we do not find any correlation between R_d and disk inclination. Fig. 4 shows that the three samples show a similar distribution in the $j_{\text{disk}}-V_{\text{flat}}$ plane, and that observed galaxies show a larger angular momentum than expectation based on the simulations of Steinmetz & Navarro (1999). It also illustrates that, due to its small disk radius, the Milky Way is deficient in angular momentum by a factor 2 compared to average local spiral with the same velocity. Conversely, M31 lies marginally above, but still well in the mean relation of local spirals.

Assuming that the SDSS sample is a good representation of local galaxies with $2.2 < \log(V_{\text{flat}}) < 2.5$, one can estimate how representative the Milky Way and M31 are in the $(M_K, V_{\text{flat}}$ and $R_d)$ volume. Fig. 5 illustrates how we identified those galaxies having a deficiency in L_K and R_d , like the Milky Way does. We find that the fraction of Milky Way-like spirals is $7 \pm 1\%$ in this volume. M31 falls just on the Tully-Fisher relation delineated by the SDSS sample (as well as by the UGC sample). However its radius (5.8 kpc) is slightly larger than the average (4.7 kpc) at $V_{\text{flat}} = 226 \text{ km s}^{-1}$. Using the same method as we use to determine the Milky Way's representativeness, we find that $30 \pm 3\%$ of the SDSS galaxies have a disk radius larger or equal to 5.8-0.4 kpc, i.e., those

FIG. 5.— M_K (above) and R_d (bottom) versus V_{flat} for SDSS galaxies (red points). Large green dots represent the position of the Milky Way and the 1σ uncertainty of both relations is shown as black dashed lines. Dotted green lines show how we select Milky Way like galaxies, which are discrepant in both L_K and disk length scale. Because of the large scatter in the R_d - V_{flat} relation, we also consider as an alternative estimate, all objects within $V_{flat}=2.2$ - 2.5 having $R_d \leq 2.3+0.6$ kpc, in gauging the representativeness of the Milky Way (see text for details).

being M31-like galaxies. Because the R_d - V_{flat} distribution is not as tight as the Tully-Fisher relation (see Fig. 5), we adopt two different schemes for estimating the fraction of MW-like (and M31-like) galaxies in the corresponding plane. One is assuming that the R_d - V_{flat} correlation is real, the other is considering only galaxies with disk radii smaller than $2.3+0.6$ kpc (for Milky Way like galaxies) and larger than $5.8-0.4$ kpc (for M31-like galaxies). Both alternatives produce similar numbers and the difference is attributed to the uncertainties discussed previously.

In summary, we find that very few galaxies have (M_K , V_{flat} and R_d) properties similar to that of the Milky Way, while M31 is far more representative. The above calculation is affected by the fact that we have assumed a much larger relative error bar ($\Delta R_d/R_d$) for the Milky Way than for M31. Applying similar relative errors for both objects (i.e., considering $\Delta R_d/R_d=0.26$), would lead to a much higher fraction of M31-like galaxies. This is consistent with the location of the two galaxies relative to the 1σ error of the two relations shown in Fig. 5. If the distributions were gaussian and independent, the location of the Milky Way outside the 1σ error is consistent with few percent of Milky Way-like galaxies, while M31 is a typical spiral.

5. THE ALMOST UNTOUCHED OUTSKIRTS OF THE MILKY WAY

We have shown that dynamical properties of the Milky Way may be quite exceptional compared to a local spiral galaxies with similar rotation speeds. Let us investigate if previous kinematic events have left some imprint on the outskirts of the Galaxy's stellar populations since those populations are most likely to show the most obvious residual effects of the merging history (dynamical relaxation times are long and so mixing of the stellar populations both in terms of chemistry and dynamically is likely to be significantly less than in the disk or inner regions of the galaxy, e.g., Font et al. 2006; Renda et al. 2005). The definition of the stellar halo by Renda et al. (2005, see also Chapman et al. 2006) is intended to include all stars within the outskirts of a galaxy (they used limiting radii ranging from 4 to 30 kpc). This definition is comparable to the “spheroid” of M31 which is used by Brown et al. (2006) to be 5 to 30 kpc from the disk minor axis. The “spheroid” of M31 is well described by a de Vaucouleurs law (Pritchett & van den Bergh 1994; Irwin et al. 2005) up to 30 kpc (Durrell et al. 2004). Given this, we have adopted the word “outskirts” to encompass the various, perhaps ill-defined definitions of what constitutes stars beyond the relatively high surface brightness disks of these spiral galaxies.

One of the most spectacular events currently under investigation in the outskirts of the Milky Way is the Sagittarius stream (Ibata et al. 1994; Majewski et al. 2003). While it is interesting to study the Sagittarius for understanding the evolution of the halo of the MW, its stellar content is very small ($2 \times 10^7 L_\odot$ in V band, see Majewski et al. 2003). The Sagittarius stream represents only a very tiny fraction of the stellar content of the Milky Way stellar halo ($2 \times 10^9 M_\odot$, see Carney et al. 1990). The stellar content of the outskirts of the Milky Way is essentially made of old stars with low metal abundance ($[Fe/H] = -1.6$, Beers & Sommer-Larsen 1995; Morrison et al. 2003, see also the review by Prantzos 2006). Conversely, the outskirts of M31 are dominated by metal-rich stars ($[Fe/H]$ from -1 to -0.8 , Mould & Kristian 1986; Rich et al. 1996; Durrell et al. 2004, and references therein). It has been argued by Kalirai et al. (2006) that stars within 30 kpc of the center of M31 are indeed part of an extended spheroid (or bulge). By itself, this property illustrates the profound difference between M31 and the Milky Way. For the Milky Way, such a chemically enriched extended spheroid which dominates the star counts up to 30 kpc does not exist. In the following we review briefly how the properties of the Milky Way outskirts (defined as a region from 5 to 30 kpc from the centre) compare with those of external spirals.

Comparing with the properties of the outskirts of Milky Way and M31 however requires some care. First, most abundance studies in the Milky Way are based on high resolution spectroscopy while color magnitude diagrams are most commonly used for stars in external galaxies. We note however that the study of, e.g., Morrison et al. (2003) shows that the agreement between abundances estimated from spectroscopic and photometric measurements are excellent. Second, the areas surveyed to derive stellar abundances are small, they may be unrepresentative of the dominate populations, and this may lead to biases in all estimates. For example, an external observer of the Milky Way might have unluckily observed the region where the bulk of the stars belonging to Sagittarius lie, and would likely conclude that the outskirts of the Milky Way are indeed enriched. However this alternative becomes more and more unrealistic given the reasonable number and variety of locations of surveyed areas in the outskirts of M31, and the insignificant fraction of the total mass within Sagittarius.

FIG. 6.— *Top*: Iron abundances estimated for the outskirts of eight spiral galaxies from Mouhcine et al. (2006) plotted against $\log(V_{\text{flat}})$ (small red points). Large green points represent the values for the Milky Way and M31. The solid line assumes $M_{\text{star}} \sim V^4$ (McGaugh 2005) and $M_{\text{star}} \sim Z^2$ following the prescription of Dekel & Silk (1986). Red dashed lines represent the range of Zibetti et al. (2004), after stacking 1047 edge-on SDSS galaxies, and assuming that their colors are dominated by red giant stars. *Bottom*: Tully-Fisher relation for the same galaxies (very small red dots represent the sample of Pizagno et al. 2006).

Mouhcine et al. (2006) have compared the abundances of outskirts of several spiral galaxies. Mouhcine et al. selected red-giant stars that lie 2 to 10 kpc along the projected minor axis of eight nearby spirals, in areas which are part of galactic outskirts although they might also be contaminated by bulge or thick disk stars. Fig. 6 shows the $\langle [\text{Fe}/\text{H}] \rangle$ of red giant stars against V_{flat} : all galaxies, except the Milky Way, show a trend of an increasing metal abundance with rotation velocity of the disk. This trend, found by Mouhcine et al., is likely explained through an examination of Fig. 6 (bottom): while massive galaxies have transformed most of their gas into stars and metals, smaller galaxies have been much less efficient in doing so, and still include a large gas fraction as indicated by their location in the Tully-Fisher relation (e.g., McGaugh 2005). Interestingly such a relation, if confirmed, requires a certain mixing of stars with different enrichment patterns in the outskirts of the galaxy, such as might be provided by a merger. The Galaxy’s outskirts are under-abundant relative to the trend line formed by external galaxies by about 1 dex implying that it has been far less enriched than those of other galaxies of the same total mass. On the other hand, M31 shares a similar location than other large spirals in Fig. 6. This strengthens our hypothesis that the properties of M31 are rather typical of large spiral galaxies while the Milky Way appears to be exceptional.

Similarly, and perhaps more generally, the results of Zibetti et al. (2004) add more credence to our hypothesis. They found, by stacking 1047 images of SDSS edge-on spirals, that the average color of stars at ≥ 5 times the disk scale length, beyond the disk minor axis, is redder by $\Delta(r-i)=0.3-0.4$ than Milky Way globular clusters (or Galactic halo stars), or after converting SDSS photometry (Jordi et al. 2006), by $\Delta(V-I)=0.45 \pm 0.1$. This discrepancy is especially large for the brightest galaxies of the Zibetti et al. sample, i.e., those with similar absolute magnitudes as the Milky Way. The brightest galaxies show the reddest stellar halo colors, accentuating this differ-

ence with the Milky Way. Zibetti et al. show convincingly that their measurements are not significantly affected by dust. If these measurements are dominated by red giant stars, such a large shift in (V-I) colors is unlikely related to an age difference between SDSS galaxies and the Milky Way, but more likely due to different metallicities (see, e.g., Lee et al. 1993). The Galactic globular clusters and halo stars are indeed very old, and a 0.45 mag shift in V-I to the red is likely due to a shift of $0.8 \text{ dex} \pm 0.2$ in $[\text{Fe}/\text{H}]$ (Lee et al. 1993). Comparing the (V-I) colors from Zibetti et al. to that of nearby galaxies studied by Mouhcine et al. allows us to place this ensemble of galaxies in Fig. 6. It is apparent that the SDSS galaxies lie within the range defined by the intermediate mass spirals, including M31. The bulk of the Zibetti et al. (2004) sample is composed of galaxies with M_i (where i refers to the i band of the SDSS) ranging from -19.5 to -22.5 (for $H_0=70 \text{ km s}^{-1} \text{ Mpc}^{-1}$). This corresponds to $\log(V_{\text{flat}})$ ranging from 1.95 to 2.35 or galaxies with rotation velocities similar to less than that of M31 and the MW (Pizagno et al. 2005).

Combined together, the above results strongly suggest that stars in the outskirts of the Milky Way have an average chemical abundance three times lower than those of most spirals within a similar mass range. Simulations show that the very low metal abundance of the outskirts of our galaxy may require the absence of any previous merger of satellites with mass larger or equal to $10^9 M_{\odot}$ (Font et al. 2006).

6. TOWARDS A FORMATION SCHEME FOR SPIRAL GALAXIES WITHIN THE CONTEXT OF DIFFERENCES BETWEEN THE MILKY WAY AND M31

In the previous sections of this paper, we have shown that perhaps the properties of the Milky Way are not representative of those of a typical local spiral galaxy. Within this context, we have used M31 as a foil to the Milky Way trying to demonstrate that it is a typical representative of the spiral galaxy population (at least for those that have rotation speeds similar to the Milky Way). Since we find a compelling case for the differing relative natures of the Milky Way and M31, we wish now to discuss and conjecture on what these differences may be telling us about galaxy formation. Unlike previous discussions of the relative characteristics of the Milky Way and M31, we wish to embed this within the context of what we know about the properties of distant galaxies.

6.1. A quiet formation history compared to a merger-driven formation history: the MW versus M31

Historically, the Milky Way and M31 were thought to be quite similar. They have the same Hubble type and similar total masses. At a given V_{flat} , we find that M31 has a stellar mass and angular momentum close to that of the average of local spiral galaxies. In contrast with this, the Milky Way has a stellar mass and angular momentum that are two to three times lower than average. Its outskirts could be even more peculiar, with stellar abundances three times lower than those of other spirals with approximately the same absolute magnitude and rotation velocity.

What renders the Milky Way so exceptional? Its peculiarities seem to be tightly linked to its “quiet” history of formation. It is interesting to compare its formation history with those of other local spirals galaxies. M31 has properties that are much closer to those of an average spiral. Let us investigate how M31, when compared to the Milky Way, may have acquired 2 times more stellar mass and 2.5 times more angular momentum.

Detailed studies of bulge, disk and outskirts of M31 have been (mainly recently) made. Recent discoveries about M31 are numerous (giant stream, large faint clumpy disk, age-metallicity of stars in the disk, characterization of the metallicities and ages of the globular cluster system, detailed measurements of the chemical abundances and ages of bulge and halo stars, etc.). Reviewing these discoveries alone would by itself require a very long manuscript. Such a detailed review is obviously beyond the scope of this paper. Let us just summarise some of the widely accepted implications of these new discoveries. Both the stream (Ibata et al. 2001) and the extended clumpy thick disk (Ibata et al. 2005) plead for an active merger history for M31. Ibata et al. (2005) suggested that either a succession of minor mergers or possibly a major merger, in both cases having occurred within the last 8 Gyrs, could explain these properties of M31.

Studies of color magnitude diagrams of disk, bulge, and halo stars provide a complementary view of the star formation history of M31. The ages for globular clusters derived from Lick indices are sensitive to the template model used for the analysis (see, e.g., Beasley et al. 2004). For example, using Thomas et al. (2003) or Bruzual & Charlot (2003) templates change the ages of the intermediate ages of globular clusters discovered by Beasley et al. (2004), from ~ 3 to ~ 6 Gyrs. Nevertheless it is widely accepted that the globular cluster system of M31 resembles that of the Milky Way, on which is superposed a population of globular clusters with intermediate ages (from less than 1 Gyr to about 8 Gyr). Interestingly, such globular clusters with intermediate ages can be formed during advanced, but still relatively obvious mergers (e.g., Schweizer 2006). In M31 this additional population represents $\sim 42\%$ of the whole GC systems and reflects a relatively recent enrichment of the outskirts of M31 by infall of another galaxy (Beasley et al. 2004). This is confirmed by the large age variance found for the properties of the stars in the outskirts (or “spheroid”, see Brown et al. 2006) of M31, which contrasts with the single, old stellar population in the stars of our own galaxy’s outskirts. The stream star ages show a peak at ~ 8 -9 Gyrs (Brown et al. 2006), while the (outer) disk stars show a peak at 5-7 Gyrs, about 2 Gyrs younger.

The differences between the Milky Way and M31 are likely due to the quiescent formation in the former case and to the merger dominated history for the latter. It is still not definite whether M31 has experienced a major merger or a succession of several minor mergers. Both merger scenarios can explain the significant fraction of stars with intermediate age and metallicity in the outskirts, as well as the fact that M31 has assembled twice the stellar mass of the Milky Way. For either alternatives, successive minor mergers (or many episodes of intense minor merging) or a few major mergers over the lifetime of a galaxy, simulations reproducing all the above observations are however not yet available. Besides this, the large angular momentum of M31 compared to the Milky Way (greater by a factor of 2.5), suggests a major encounter. Successive and numerous minor mergers are likely to be less efficient in producing large angular momentum⁵. Another argument, given by Brown et al. (2006), is: “if the Andromeda spheroid is the result of many smaller mergers that did not occur in the Milky Way, one must ask why there is such a statistically significant distinction between the merger histories of

two similarly-sized spirals in the same galaxy group.” Ibata et al. (2005) also favored a major encounter to interpret the homogeneous chemical properties of the “extended clumpy disk”.

How credible is the hypothesis that M31 had experienced a major merger in the past? If the M31 stream is a relic of such an event, it might have occurred ~ 8 Gyrs ago, as was suggested by Brown et al. (2003). Simulations of the stream have focused on a very recent (0.5 Gyr old) merging of a $10^9 M_\odot$ dwarf (Font et al. 2006). Brown et al. (2006) suggested it would be useful to test whether the stream could actually be due an earlier event in the history of M31, as well as whether such a giant stream would still be evident after 8 Gyrs. Indeed, such a major merger can explain the similarities between the stream and the populations of the outskirts (Brown et al. 2006) since both will be polluted in a similar way during the merging process. This is in contrast with expectations from a scenario involving multiple minor mergers for which age-metal signature should be far less uniform than what it is observed. Eight Gyrs ago, the progenitor of M31 was unavoidably a much smaller galaxy than it is today: as noticed by Ibata et al. (2005), an event involving a galaxy of the M33 size would have been a major merger event. Is such an ancient major merger event realistic knowing that M31 possesses a large thin disk (Morrison et al. 2004)? On the basis of the properties of the old disk globular clusters in comparison, Morrison et al. (2004) have argued that the thin disk is indeed old. However, their arguments have been contradicted by much lower age estimates of the same objects (Beasley et al. 2004). The ages of disk stars, 5-7 Gyrs, are consistent with a disk built predominately during ≤ 2 Gyrs after a major merger event: simulations predict a rapid formation of the new disk after a major gas-rich merger event (but also including the effects of substantial feedback Governato et al. 2006; Robertson et al. 2006).

The large (specific) angular momentum of M31 (compared to that of the Milky Way), the similarity of halo and stream stellar populations, the difficulty in having a succession of many minor encounters in M31 and very few or none for the Milky Way, all favour a relatively recent, ~ 8 Gyrs ago, major merger having a substantial impact on the final characteristics of M31. Interestingly a similar conclusion has been reached by Durrell et al. (2004). They noticed that a major merger scenario naturally explains the relative metallicity distribution functions of both the stars in the outskirts and globular clusters. They also suggest similarities between the M31 spheroid and the outer part of giant ellipticals. As a matter of interest, M31 falls precisely on the relation between black hole and bulge mass as for elliptical galaxies (e.g., Tremaine et al. 2002). This suggests that, even on much smaller scales than that of the outskirts, a major merger might have had a substantial impact on the properties of M31. Notice specifically that the black hole-bulge relationship has been explained in the frame of major mergers, intimately connecting a quasar phase of galaxies (Hopkins et al. 2006a,b) to the overall evolution of galaxies (Springel & Hernquist 2005) with AGN feedback being a necessary and crucial process responsible for this interplay.

In summary, one can explain the differences between the Milky Way and M31 by the absence of significant merger event(s) over the last 10-11 Gyrs for the former. M31 has a stellar mass and a chemical enrichment in the stars in its outskirts typical of local spiral galaxies. Its angular momentum is 1.25 times that of an average SDSS galaxy at same V_{flat} .

⁵ Note that this argument also applies if one considers the spin parameter, because the total masses of M31 and Milky Way being so similar, their ratio of spin parameters scales with that of their angular momentum.

Besides this, the Milky Way has a deficiency of a factor two in both stellar mass and angular momentum, when compared to a similar average. Accounting for this, galaxies as or more exceptional than the Milky Way represent only 7% of all local spirals. Because of the remarkable properties of the relatively unpolluted Galactic outskirts, the fraction of Milky Way-like galaxies may be even lower. It is then probable that most local spirals, like M31, have experienced more and perhaps, later mergers than the Milky Way. In such a case, the differences in the formation histories of the Milky Way and M31 are simply reflected in the differences between the properties of the Milky Way and those of the bulk of local spirals.

6.2. *Does the Exceptionally Quiet Merger History of the MW Imply it Grew through Secular Processes?*

Advocating a new scenario of spiral formation means we have to break some “taboos” – the main one being the fact that Milky Way may be an exception rather than the rule. The widely accepted assumption that a major merger would unavoidably lead to an elliptical is perhaps no longer tenable: accounting for the large number of major mergers that have apparently occurred since $z=3$ would imply that all present-day galaxies should be ellipticals. This is obviously not the case. So it is likely that disks either can survive or are “re-built” after a major merger, through whatever mechanism as yet perhaps unknown in detail (see, for example, Robertson et al. 2006).

Many simulations have the implicit assumption that most of the star formation in intermediate mass galaxies had occurred well before $z=1$. This is however not correct: nearly half of their present-day stellar masses has been formed since that epoch, as shown by Hammer et al. (2005), or Bell et al. (2005). But more than this, to reproduce the zero-point of the local Tully-Fisher relation within the framework of the standard gas accretion model, requires spin parameters (λ from 0.06 to 0.08) larger than those expected for dark matter halos ($\lambda=0.042$ on average, see Pizagno et al. 2005; Dutton et al. 2006). This discrepancy has led Dutton et al. (2006) to relax the adiabatic contraction hypothesis of the standard scenario. They assume instead that the halo expands during a major merger and must lead to a new disk being formed (or perhaps a pre-existing disk preserved in some way), with a clear reference to the simulations of Robertson et al. (2006). It seems more and more evident that the formation of disk galaxies requires a larger influence of mergers than hypothesized in the standard scenario.

The Milky Way being an exceptionally quiet galaxy alters the validity of the standard scenario of spiral formation which has been mostly based on our Galaxy’s properties. This being the case, the situation is in reality worse for the general validity of this scenario. Indeed, giant stars of the Galactic bulge show large α/Fe ratio indicating a fast (~ 1 Gyr) formation of the bulge (Zoccali et al. 2006; Lecureur et al. 2006). If confirmed, it seems that the Milky Way’s bulge formed at very early epochs through the merger of large clumps (or progenitor galaxies), with the disk being built (or rebuilt) later on. This is in stark contrast with a primordial condensation of gas into a disk which then forms stars, the main assumption in the standard scenario.

More interesting perhaps is to consider the Milky Way as an archetype of a galaxy having experienced no merging event since the last 10-11 Gyrs. We assume here that very small encounters such as the present disruption of Sagittarius (with a mass of less than 1% of that of the Milky Way) are not suffi-

cient to significantly enrich the stellar halo in mass or substantially alter its average metallicity. Font et al. (2006) indeed argue that the very low metal abundance of the Galactic stellar halo requires the absence of any previous merger of satellites with mass larger or equal to $10^9 M_\odot$. If correct, this implies that the Galactic disk may have mostly grown by an approximately smooth gas accretion, or, in other words, by secular evolution (see also Croton et al. 2006, who suggest that such infall may be sufficient to build the Milky Way disk). In the following, we consider that secular evolution includes either smooth gas accretion or accretion of small satellites. Let us consider that the Galactic disk has been formed by secular evolution and that the Galactic bulge (in which $\sim 25\%$ of the stellar mass is locked, see Flynn et al. 2006) was formed by an early merger. If the fraction of the mass of both the Milky Way and M31 that grew through secular evolution – accretion of gas and of small satellites – have been similar, since they inhabit the same group, we can use the difference in stellar masses to estimate the likely contribution of smooth gas accretion in general. The difference between M31 and Milky Way stellar masses can be accounted if $\sim 36\%$ (estimated with the ratio $M_{\text{star}}^{\text{MW disk}}/M_{\text{star}}^{\text{M31}}$) of the mass assembly of M31 is due to secular evolution, while 64% may be directly linked with mergers. Since M31 has a typical stellar mass amongst local spirals of the same total mass (also including the dark matter component which influences their dynamics), this balance may apply to most spirals, or at least those inhabiting environments of similar density as the Local Group.

6.3. *The Spiral Rebuilding Hypothesis: Formation of spiral galaxies after major mergers?*

The mass assembly of typical spirals, including M31, has been probably driven predominantly by mergers and that their assembly history might not be best represented in the characteristics of the Milky Way. Galaxies with approximately the same rotation speeds as the MW also show larger angular momentum. Those can be produced by a single major merger while it is difficult to reconcile with a succession of minor mergers. Here we investigate how a scenario with major mergers can be reconciled with observations.

The spiral rebuilding scenario was proposed by Hammer et al. (2005) to explain the observations of the distant galaxies. Specifically, this hypothesis was used to explain for distant galaxies the simultaneous evolution of the global stellar mass, Luminosity-Metallicity relationship, pair statistics, evolution of the IR light density, colors of spiral cores (bulges?), evolution in the number density of spheroids and spiral galaxies, and evolution in the fraction of peculiar galaxies (mergers and compact). The spiral rebuilding scenario is consistent with all these evolutionary trends, while a scenario for which the stellar mass formation is dominated by minor encounters (“collisional starbursts”, Somerville et al. 2001), has difficulties in reproducing in particular the evolution of the IR light density, number density of peculiar galaxies and spiral core colors.

In such a framework, the question of the representativeness of the Milky Way may simply be explained by the low fraction of galaxies that have escaped a major merger since $z\sim 3$. Galaxies like the MW with a quiet merger history are expected to have, on average, a lower stellar mass, a lower angular momentum and a less enriched stellar halo for their rotation speed, but still could be the product of a major merger. Conversely, the representativeness of M31 compared to the 50 to 75% fraction of galaxies of similar masses, may be a result of the ubiquity of major mergers since $z=1$ (see §1) and their

significant influence in determining the properties of spirals at the current epoch. The differences between the MW and M31 may be therefore simply due to the epoch of the last equal or nearly equal mass merger. In the case of the MW, perhaps the last major merger occurred well before $z=1$, while for M31 it is likely that it occurred around or after $z=1$.

Major advances in simulations have provided a theoretical framework for the disk rebuilding scenario. Cox et al. (2006) have shown that the remains of dissipational mergers have significant rotation and angular momentum compared to dissipation-less mergers. Even without efficient feedback, ellipticals, when formed after a merger, possess a seed for the subsequent formation of a rotationally supported disk. Robertson et al. (2006) have shown that gas dominated mergers (gas fraction larger than 50%) can produce remnants with disks of sufficiently high angular momentum (unlike simulations that do not include gas-rich major mergers to explain the large angular momentum of disks; e.g., Steinmetz & Navarro 1999). The importance of high gas fraction has been already been suggested by Hammer et al. (2005), since it is the gas expelled through the impact of strong feedback which subsequently feeds the newly formed disk and provides the necessary rotational support and sufficient specific angular momentum (e.g., Robertson et al. 2006). Since stellar mass density of galaxies has nearly doubled since $z=1$, the condition that galaxies have large gas fractions must be the case on average. Evolution of the gas content in galaxies is also observed, although indirectly, from the observed evolution of the gas phase metal abundance in distant galaxies. Liang et al. (2006) have estimated that the gas content in intermediate mass galaxies at $z\sim 0.6$ was two times larger than in galaxies at the current epoch. Erb et al. (2006) have found, at $z\sim 2$, gas fractions ranging from 0.2 to 0.8.

Although the consequences of adopting this scenario need to be more accurately evaluated, the rebuilding disk scenario is becoming more and more viable. Regardless, observations show that there is sufficient gas at redshifts less than one out of which disks could be rebuilt. The rebuilt disks and bulges after a major merger should be compared to observations of present-day galaxies in a realistic way, i.e., after accounting for further gas accretion (or secular evolution) which may essentially feed the disk (see also Croton et al. 2006). Thus the rebuilding disk scenario may only require some tuning of the assumptions already made in most simulations. In essence, this scenario implicitly solves both problems of the standard scenario (e.g., disk stability to further collisions and angular momentum), because subsequent collisions help to generate large angular momentum as it is observed in local spirals. Late epoch merging generally results in disks with higher angular momentum than disk which had their last major merger earlier in the history of the Universe as perhaps did the Milky Way. Besides explaining the difference in angular momentum, it may also explain why the average metallicity of stars in our halo are less than that of typical spirals at the same rotation speed and other characteristics of the Milky Way's halo.

However, this alternative to the standard scenario has not been carefully considered in the literature or through simulations, possibly because it appears too exotic or too disturbing. A possible caveat could be the significant fraction of LIRGs (galaxies with high IR luminosities of $\gtrsim 10^{11} L_{\odot}$) at high redshift showing spiral morphologies (Melbourne et al. 2005; Bell et al. 2005). However, the rebuilding disk phase corresponds to a phase of strong gas infall (from gas left over from the merger and by a gradual cooling of the hot halo gas),

during which the galaxy may well have the appearance of a LIRGs with spiral morphology.

Is there observational evidence for a subsequent disk rebuilding phase occurring later, after the merging? At least an interesting clue can be derived from recent observations of the evolution of the Tully-Fisher relation. One can compare the pair fraction ($5\pm 1\%$ of $z=0.6$ galaxies, see §1) to the higher fraction (26%, Flores et al. 2006) of $z=0.6$ galaxies having complex velocity fields, the later being probably associated with merger remnants from comparison to numerical simulations (Puech et al. 2007). Assuming 0.35 Gyr as the characteristic time for a real pair to actually merge (see §1), implies a remnant phase lasting from 1.5 to 2 Gyrs, in a relatively good agreement with expected times needed to rebuild a significant disk after an efficient feedback phase (Robertson et al. 2006; Governato et al. 2006). A more quiescent history of cold and clumpy gas flow has been also been investigated for disk formation (Dekel & Birnboim 2006). Such a scenario however needs to show how it succeeds in reproducing the strong evolution of violent star formation with epoch (i.e., the strong number density evolution in galaxies with substantial IR luminosities, $L_{IR} \gtrsim 10^{11} L_{\odot}$) and in solving the angular momentum problem. Assuming collisions of large enough gas clumps might succeed in explaining the characteristics of distant galaxies, although it would at any rate be close to a scenario hypothesizing a large fraction of major mergers at intermediate redshifts as is observed.

7. CONCLUSION

Compared to local spirals with similar rotation velocities, the Milky Way has a significant deficiency of stellar mass, angular momentum and chemical abundances in stars in its outskirts. We have argued that these differences can be interpreted as being due to the exceptionally quiet formation history of the Milky Way compared to other spirals at comparable rotation velocities. After the rapid building of its bulge, more than 10 Gyr ago, the disk of the Milky Way has been formed inside-out mostly through smooth gas accretion, in a secular mode. In the same dynamical mass range, the bulk of spiral galaxies, including M31, have accreted most of their mass and angular momentum through a more recent and active merger history. In other words, other galaxies may have populations of stars in their outskirts similar to the Milky Way but to which a significant component would have been accreted later through further episodes of mergers. Combining results from observations of distant galaxies (merger rate and evolution of LIRGs) to those of local galaxies (Tully-Fisher and angular momentum), we have hypothesized that most spiral galaxy disks are “rebuilt”. The timing of this rebuilding and how many episodes of rebuilding are also crucial parameters within this hypothesis. In such a scenario, to reproduce the properties of the Milky Way, the disk of the Milky Way was built (or rebuilt if it had a pre-existing disk) at a much earlier epoch (~ 10 Gyrs ago) than the general population of local spiral galaxies. Thus, the standard scenario of disk formation may not even apply to the Milky Way.

The major advantages of the disk rebuilding scenario are that it may solve simultaneously various problems such as the so-called angular momentum problem (major merger are very efficient to produce angular momentum), the large fraction of stellar mass produced in LIRGs since $z=1$ (major merger are an efficient way to produce episodic strong star formation), and the chemical abundances of stars in the outskirts of spiral galaxies (by efficient mixing). However, the most important

point of this paper is that it may also naturally explain why the Milky Way is so exceptional in its properties when compared to other spirals. Specifically, we think that adopting the spiral rebuilding scenario for understanding the evolution of spiral has a number of significant consequences. These are:

- M31 appears to be a typical spiral, emphasising the need to investigate further its precise formation history in order to understand how the majority of spiral galaxies may have formed; What differences in the final characteristics result from the exact time at which the rebuilding occurs?
- That the Milky Way had an exceptionally quiet formation history, having escaped any major merger (and possibly a significant number of minor mergers) during the last 10-11 Gyrs; Milky Way like galaxies correspond to only 7% of local spirals, and possibly much less;
- Suggests the need for modelling the formation history of spirals using a superposition of a “quiet” history like that of the Milky Way with an active history of merging, which could be responsible for $\sim 2/3$ (perhaps more) of the stellar mass;
- Explains the failure of the standard scenario for spiral formation which is unable to reproduce the properties of spiral galaxies, including their stellar mass-Tully-Fisher relation, their high angular momentum and the chemical abundances of stars in their outskirts;
- There is a reasonable chance that the spiral rebuilding scenario can reproduce most of the observed properties of local spirals, as well as those of their progenitors at large distances.

Galaxy simulations are certainly needed to investigate the accretion history of spiral galaxies. The evidence for a scenario where the evolution of disk galaxies is driven predominantly by mergers rather than by other secular processes, allows us to suggest that the key question is to now gauge the relative impact of minor and major merger in shaping spiral galaxies as we seen them today. Observationally, M31 is certainly the best target for a robust investigation to determine the past history of a typical spiral galaxy. In addition, follow-up of the pioneering modelling work of Robertson et al. (2006) and Governato et al. (2006) would be also very valuable in understanding the role of mergers (both major and minor) in disk galaxy evolution. Major mergers with a variety of mass ratios and angular momentum vectors should be investigated to see if then can reproduce the characteristics of spiral galaxies in detail. Such simulations must include realistic amounts of gas for the progenitors within a redshift range $z=0.5-3$ and more observational effort should be expended in determining this parameter. Subsequently, such models could be scaled to the observed fraction of mergers (and merger remnants) and by observationally determined distributions of mass ratios and angular momentum vectors. By assuming after the last major merger, a realistic rate of “smooth” gas accretion, would let one investigate whether the re-shaped disks and bulges are consistent (or not) with the observed properties of the ensemble of bulges and disks in present-day galaxies.

The authors wish to thank F. Spite and M. Spite, and especially R. Ibata and A. Robin, for helpful comments, discussions, and carefully reading several versions of this manuscript. Their effort is greatly appreciated. We thank M. Steinmetz for kindly sharing the results of his work with us.

APPENDIX

ON THE ROTATIONAL VELOCITY OF THE MILKY WAY

As noticed by Flynn et al (2006), the Tully Fisher relation is so steep, that with a value of $V_{flat}=185 \text{ km s}^{-1}$, the Milky Way would nicely fall along and within the scatter of the Tully-Fisher relation of external galaxies (see Fig. 2). Indeed estimates of the local circular rotation, Θ_0 , values down to 185 km s^{-1} (Olling & Merrifield, 1998) and up to 235 km s^{-1} (Reid & Brunthaler, 2004) or even 255 km s^{-1} (Uemura et al., 2000) have been reported. These estimates are highly degenerate as they depend on the value of R_0 – the distance to the Galactic Center. This is well illustrated in Figure 1 of Olling & Merrifield (1998). Here we consider various combinations of (Θ_0, R_0) determined or adopted by different studies. They are (185, 7.1), (235, 8.0) and (255, 8.5) for Olling & Merrifield (1988), Reid & Brunthaler (2004) and Uemura et al. (2000), respectively. The most accurate and direct estimate of $R_0 (= 7.94 \pm 0.42 \text{ kpc})$ has been determined by Eisenhauer et al. (2003) on the basis of proper motions around the black hole in the Galactic center. This estimate was further refined in Eisenhauer et al. (2005, $R_0 = 7.62 \pm 0.32 \text{ kpc}$). Notice that these values are in agreement with the best overall estimate of Reid (1993) made by combining previous estimates before the early 90s. Using the Eisenhauer et al. (2005) value of R_0 , Brunthaler et al. (2006) derive $\Theta_0 = 225 \pm 10 \text{ km s}^{-1}$, the uncertainty depending mostly on the uncertainty in the estimates of R_0 .

A robust measurement of the relative rotational velocity of the Sun to the halo has been made by Sirko et al. (2004) who find $222.1 \pm 7.7 \text{ km s}^{-1}$. This measurement was based on an analysis of the kinematics of 1170 blue horizontal branch stars in the Galactic halo. Solar velocities significantly lower than the IAU standard would correspond to a halo with significant counter rotation (Sirko et al. 2004). Conversely, the rotation velocity of the Galactic halo is found to be in the same sense as the disk rotation, and marginally consistent with no rotation (Sirko et al. 2004 and references therein). Extreme values for the local circular velocity are also excluded by open cluster velocities in the Milky Way (Frinchaboy & Majewski 2005). The evidence seems to favor a value of the rotation velocity of the Milky Way that is close to the IAU standard and we see no need to adopt a different value.

To compare Milky Way to external galaxies requires us to determine what an external observer would estimate for V_{flat} . Indeed within the range of reasonable (Θ_0, R_0) values (Brunthaler et al. 2006; Eisenhauer et al. 2005), the fit of the Milky Way rotation curves (see Fig. 1 of Olling & Merrifield 1988) shows a flat or a slightly rising curve. To some extent, this contrasts with the rotation curve of M31 which smoothly decrease from 259 km s^{-1} at 10 kpc to 226 km s^{-1} at large radii (Carignan et al. 2006). Such a decline is likely due to the effect of the prominent bulge of M31. Other considerations are also very instructive. It has been argued by Evans & Wilkinson (2000) that, contrary to earlier ideas, the halo mass of the Milky Way could be equal or even

higher than that of M31. Because V_{flat} is intimately linked with the total mass of a galaxy (see §3), under this hypothesis, it is reasonable to adopt for the Milky Way rotation speed (220 km s^{-1}) that is close to that of M31 (226 km s^{-1}). In summary, the deficiency of stellar mass of the Milky Way compared to M31, and hence to external galaxies, appears to be particularly robust.
